

Graph Theory & Surface Reconstruction

Jenny Zhen

April 25, 2013

Abstract

The purpose of this paper is to utilize a technique to recreate models of 3-D objects. This process is referred to as surface reconstruction, which replaces a set of sample points using a faceted geometric model. Multiple concepts from graph theory are used, specifically duals of graphs, n -regular graphs, bridgeless graphs, and matchings. Weighted and unweighted mergings of faces are also discussed to address issues of distortion resulting from mergings.

Introduction

The paper will refer to the triangulation of a 3-D surface given in the figure below.

Figure 1: Triangulation of a torus.

The figure resembles a torus, which is created by revolving a circle along a line made by another circle. Divisions of polygonal faces that form the torus produces triangular faces throughout the torus. This triangular mesh will serve as the basis for the surface reconstruction method that will be explained later in this paper.

Dual Graph

By definition, the planar dual of any planar graph, G , can be constructed by placing a vertex in each region of G and then adding edges between regions that share a border. The planar dual is denoted as $D(G)$.

If a dual of the torus is to be constructed, the same procedure to create the dual of a planar graph will be used. A point will be placed in each of the triangular faces, then lines between pairs of vertices would be placed, if and only if, the corresponding faces share a common side. The dual of the torus, G , is constructed below.

Figure 2: Dual of a torus, G .

As shown in the figure, the triangular faces of the original torus are hexagonal faces in the dual of the torus.

n-regular Graph

A graph is considered n -regular if every vertex in the graph is incident to exactly n edges.

The dual of the torus is a 3-regular graph. According to the definition, that would mean that every vertex in the dual of the torus, G , is incident to exactly 3 edges. The graph of the dual is a 3-regular because each face in the original graph is a complete graph, K_3 , in which each vertex is connected to all the other vertices. A K_3 graph consists of 3 vertices that all have degree 2. The dual of a K_3 is just one vertex inside the cycle and one vertex on the outside of the cycle, which represents the infinite region. Each edge in K_3 has an edge in the dual graph crossing the corresponding edge of K_3 to connect those two vertices, as shown below.

Figure 3: Dual of a complete graph, K_3 .

By taking the dual of groups of K_3 , a similar concept is used to connect the vertices for each region, excluding the infinite region. As a result of the three edges in each K_3 , each vertex representing one region has three incident edges in the planar dual graph of each K_3 . Thus, the dual of the torus is a 3-regular graph.

Bridgeless Graph

A graph is considered bridgeless if the removal of any single edge does not disconnect the graph.

The dual of the torus is bridgeless because the dual does not contain a cut-edge, whose removal would increase the number of components. Since the dual consists of a group of cycles, C_6 , the edge connectivity of the dual would have to be, at minimum, the edge connectivity of C_6 . The edge connectivity of C_6 , $\kappa'(C_6)$, is greater than or equal to two because C_6 does not contain a cut-edge. As a result, the edge connectivity of the dual is at least two, as shown below.

Figure 4: Connectivity of C_6 .

Removal of one edge in the left graph of C_6 does not disconnect C_6 .
Removal of two edges in the right graph of C_6 disconnects v from C_6 .

Since a grouping of C_6 in the dual adds one edge to each vertex, the edge connectivity of the dual is increased to three. That edge is one extra edge needed to increase the number of components. As a result, the removal of at least three edges is required to disconnect the dual of the torus. Thus, the dual of the torus is bridgeless because the removal of just a single edge does not disconnect the graph.

Perfect Matching

A matching for a graph is a set of disjoint edges, in which no two edges share a common vertex. A perfect matching for a graph, G , is a set of matching edges, M , such that each vertex in $V(G)$ is an endpoint of some edge in M .

Petersen's Theorem

According to Petersen's Theorem, every 3-regular bridgeless graph has a perfect matching.

As proven in the two sections above, the dual of the torus, G , is a 3-regular bridgeless graph. Thus, the dual of the torus must have a perfect matching.

Matching of a Single Face

Since all of the faces in the dual of the torus is a grouping of C_6 , the matching of the dual relies on the matching of a single C_6 . The perfect matching of a C_6 requires every vertex in C_6 to be the endpoint of an edge in the set of matching edges, M . This perfect matching can be created by adding every other edge in the cycle to the set of matching edges. As shown below, the set of matching edges, M , is $\{e_1, e_3, e_5\}$.

Figure 5: Perfect matching of C_6 .
Edges in the set of matching edges are colored green.

Matching of Multiple Faces

With a group of C_6 , the perfect matching of the center, $center_1$, C_6 is the just a perfect matching of a single C_6 (as shown in Figure 5). The surrounding C_6 alternate between single C_6 perfect matchings and single C_6 with none of its edges taken as matching edges. Alternatively, it can be viewed with the center, $center_2$, being a single C_6 with none of its edges taken as a matching. The surrounding C_6 are all perfect matchings of a single C_6 .

Both ways of viewing the perfect matching are below.

Figure 6: Perfect matching for a group of C_6 .
Edges in the set of matching edges are colored green.

Matching of the Dual

Either way, the group of C_6 is a perfect matching because every vertex is an endpoint of an edge in the set of matching edges. Even the individual C_6 that do not have any edges in the matching set have every single one of its vertices as endpoints of edges in the set because its adjacent C_6 have already fulfilled the requirements for the vertices.

If the groupings of C_6 are expanded to include all of the C_6 faces in the dual of the torus, there will exist a perfect matching for the dual of the torus, as shown below.

Figure 7: Perfect matching for the dual of a torus.
Edges in the set of matching edges are colored green.

B-Spline Construction

As mentioned before, a set of sample points is collected and then fit into a triangular mesh used for the surface reconstruction.

A method of surface reconstruction used by Matthias Eck and Hugues Hoppe is known as the B-Spline construction method. A problem with this method is that it requires quadrilateral faces instead of triangular faces. To utilize that method, the triangulation for the torus would need to be converted to contain quadrilateral faces only.

Face Merging

One method of converting triangular faces into quadrilateral faces would require the merging of faces. Pairs of faces are merged, if and only if, there is a matching edge connecting vertices in the corresponding faces.

Torus

Using the perfect matching of the dual of the torus from Figure 7, the merging of the faces is drawn below.

Figure 8: Face merging for the dual of a torus.
Edges in the set of matching edges are colored green.
Edges in the set of merged faces are colored red.

As shown above, the 3-D model of a torus is converted from a model with triangular faces to one with quadrilateral faces. The B-Spline construction method can now be used on the model of the torus.

3-D Closed Surface

The method of converting triangular faces into quadrilateral faces works for any 3-D closed surface, not just a torus. This can be proven by looking at a small portion of a surface with

triangular faces. As long as a perfect matching is made on the surface, each triangular face can be paired with another triangular face, if and only if, there is a matching edge between the two faces. The perfect matching guarantees that all faces are paired, as shown below.

Figure 9: Face merging for a 3-D surface with triangular faces.

Edges in the dual of the surface form hexagonal faces.

Edges in the set of matching edges are colored green.

Edges in the set of merged faces are colored red.

Quadrilateral faces are colored blue, pink, and orange.

Since the 3-D surface is a closed surface, the edges of the surface in Figure 9 extend outwards until it meets faces that close the surface. The merging, as shown, is a pattern that is extendable to the rest of the 3-D closed surface's faces. Thus, the method of converted triangular faces into quadrilateral faces works for any 3-D surface, as long as it is closed (and contains a perfect matching.)

Weighted Merging

By merging faces in a model, a distortion is created in the model. In order to minimize the amount of distortion, a choice in the pairs of faces to merge is critical to maintaining a model that resembles the original surface.

Figure 10: Model of the face of a cat.

Using Figure 10 as reference, the merging of two faces forming the cat's eye causes much more distortion to the model because the two faces are raised. However, the merging of two faces on the cat's ear would not greatly affect the shape of the model because those two surfaces are nearly flat.

One strategy to minimize the distortion of the model is to assign weights to each face. If a face has a high possibility of distortion (raised faces; steep slope), the face is assigned a high weight. A face with a low possibility (flat faces; no slope) will be assigned a lower weight. When a perfect matching and merging are being created, the weights of the faces are taken into consideration when assigning matchings and mergings.

The algorithm for this method would be as follows:

1. Assign weights to all faces based on their possibility of distortion.
2. Starting with the faces with low weights, assign matching/merging.
3. Repeat until the weights of all pairs of faces meet a desired threshold.

An example of a weighted, selective merging is below.

Figure 11: Selective merging based on weight of the faces.
Edges in the dual of the surface form hexagonal faces.
Edges in the set of matching edges are colored green.
Edges in the set of merged faces are colored red.
Quadrilateral faces are colored blue, pink, and orange.

In Figure 11, not all of the faces were merged. Only the pairs of faces with individual weights up to a selected threshold of 4 were merged. Using this method, the distortion of the model is kept to a minimum so that the original surface could be preserved as much as possible.

Conclusion

It can be concluded by having a graph whose dual is both 3-regular and bridgeless, a perfect matching exists for the dual of that graph. That perfect matching allows a surface containing only triangular faces to be converted to a surface containing only quadrilateral faces by merging faces connected by matchings. The method described works for any 3-D closed surface containing triangular faces. However, the merging of those faces need to the resulting amount of distortion into consideration. The strategy described can serve to reduce the amount of distortion by providing a means of selective merging based on weighted faces.
